 - Binary Search Tree Node Deletion
 - Uses for Binary Search Trees
 - Huffman Encoding
 - Balanced Trees

Binary Trees, Cont.

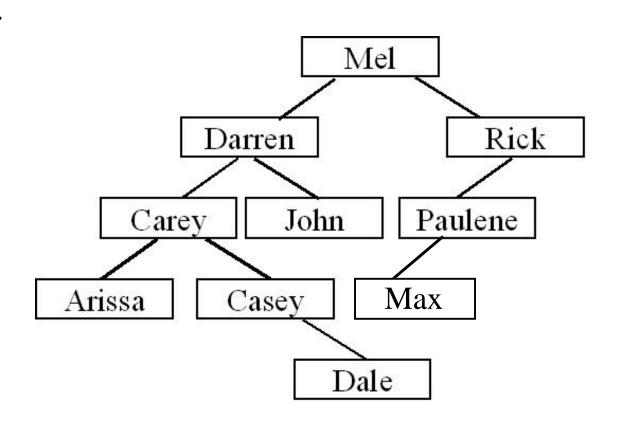

Binary Tree Review

Question #1: Is the above tree a valid binary search tree?

Question #2: How

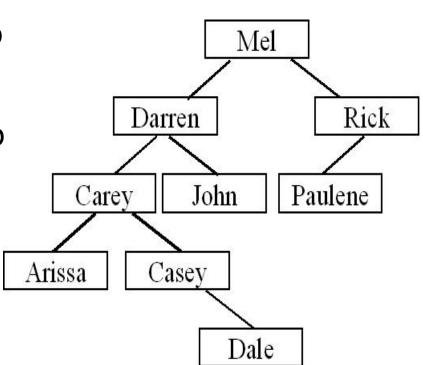

about now?

Binary Search Tree Insertion Review

Question #1: How would you go about inserting "Cathy"

Question #2: How would you go about inserting "Priyank".

Deleting a Node from a Binary Search Tree

By simply moving an arbitrary node into Darren's slot, we violate our Binary Search Tree ordering requirement!

Carey is NOT less than Arissa!

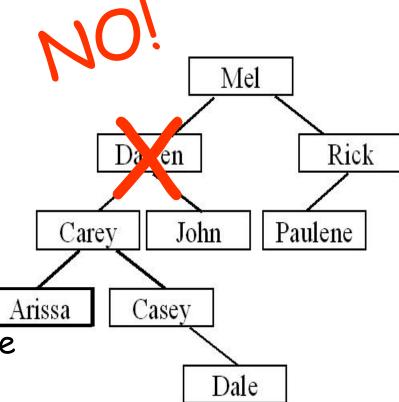

Next we'll see how to do this properly....

Now how do I re-link the nodes back together?

Can I just move Arissa into Darren's old slot?

Hmm.. It seems OK, but is our tree still a valid binary search tree?

It's not as easy as you might think!

Deleting a Node from a Binary Search Tree

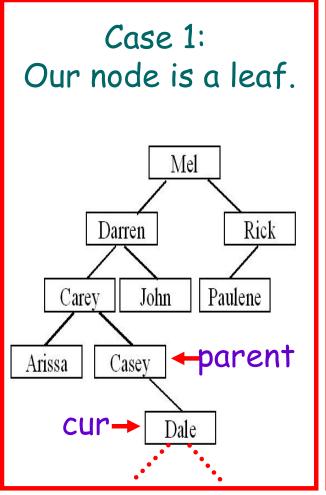

Here's a high-level algorithm to delete a node from a Binary Search Tree:

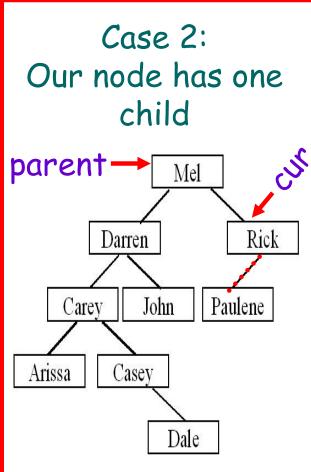

Given a value V to delete from the tree:

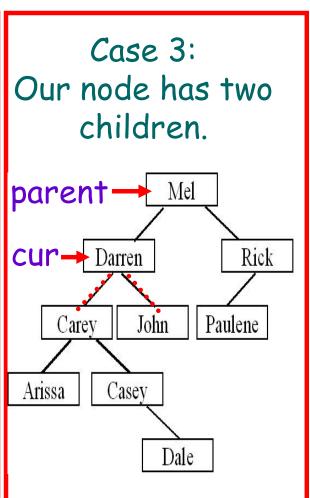

- 1. Find the value V in the tree, with a slightly-modified BST search.
 - Use two pointers: a cur pointer & a parent pointer
- 2. If the node was found, delete it from the tree, making sure to preserve its ordering!
 - There are three cases, so be careful!

BST Deletion: Step #2

Once we've found our target node, we have to delete it. There are 3 cases.

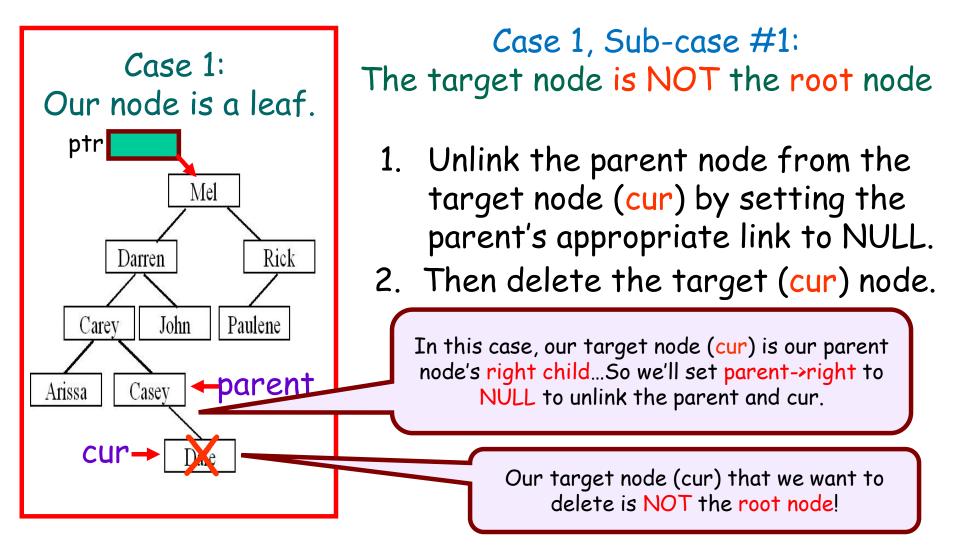

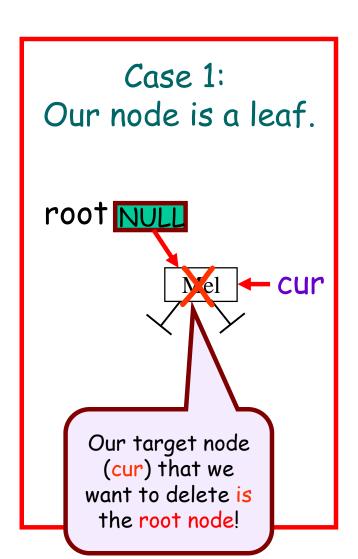

Step #2, Case #1 - Our Target Node is a Leaf

Let's look at case #1 - it has two sub-cases!

Step #2, Case #1 - Our Target Node is a Leaf

Let's look at case #1 - it has two sub-cases!

Case 1, Sub-case #1: The target node is NOT the root node

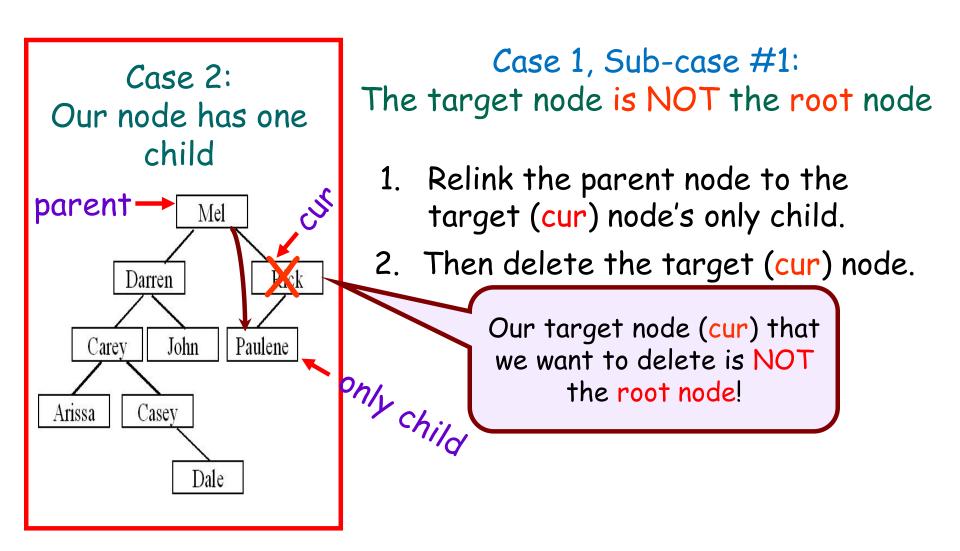

- 1. Unlink the parent node from the target node (cur) by setting the parent's appropriate link to NULL.
- 2. Then delete the target (cur) node.

Case 1, Sub-case #2: The target node is the root node

- 1. Set the root pointer to NULL.
- 2. Then delete the target (cur) node.

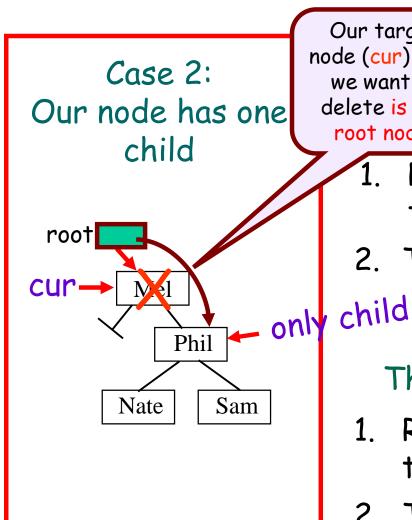

Step #2, Case #2 - Our Target Node has One Child

Let's look at case #2 now... It also has two sub-cases!

Step #2, Case #2 - Our Target Node has One Child

Let's look at case #2 now... It also has two sub-cases!

Our target node (cur) that we want to delete is the root node!

Case 1, Sub-case #1: et node is NOT the root node

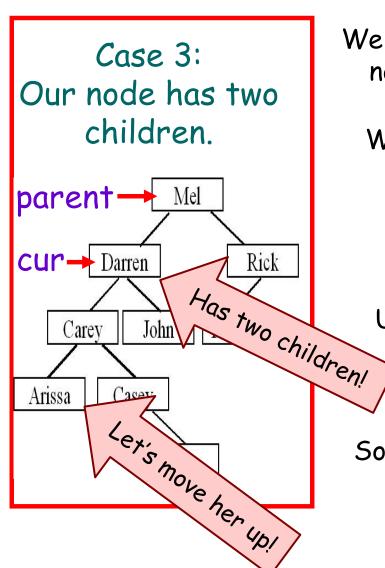

- 1. Relink the parent node to the target (cur) node's only child.
- 2. Then delete the target (cur) node.

Case 1, Sub-case #2: The target node is the root node

- Relink the root pointer to the target (cur) node's only child.
- 2. Then delete the target (cur) node.

Step #2, Case #3 - Our Target Node has Two Children

Let's look at case #3 now. The hard one!

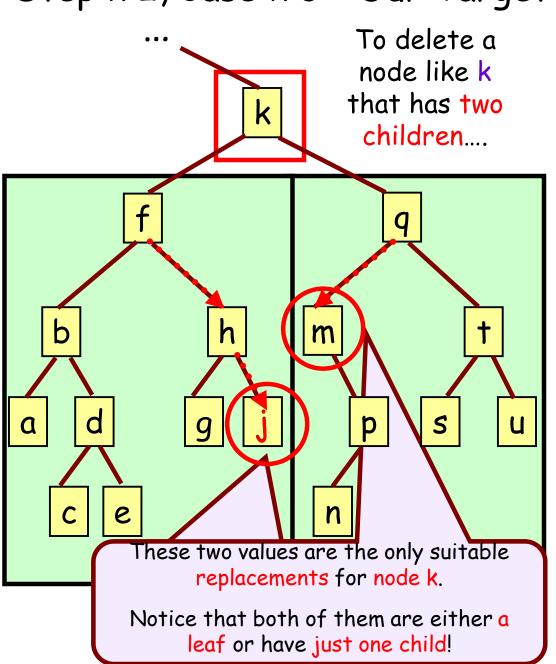

We need to find a replacement for our target node that still leaves the BST consistent.

We can't just pick some arbitrary node and move it up into the vacated slot!

For instance, what if we tried replacing Darren with Arissa?

Utoh! If we replace Darren with Arissa, our BST is no longer consistent!

So, when deleting a node with two children, we have to be very careful!

We don't actually delete the node itself!

Instead, we replace its value with one from another node!

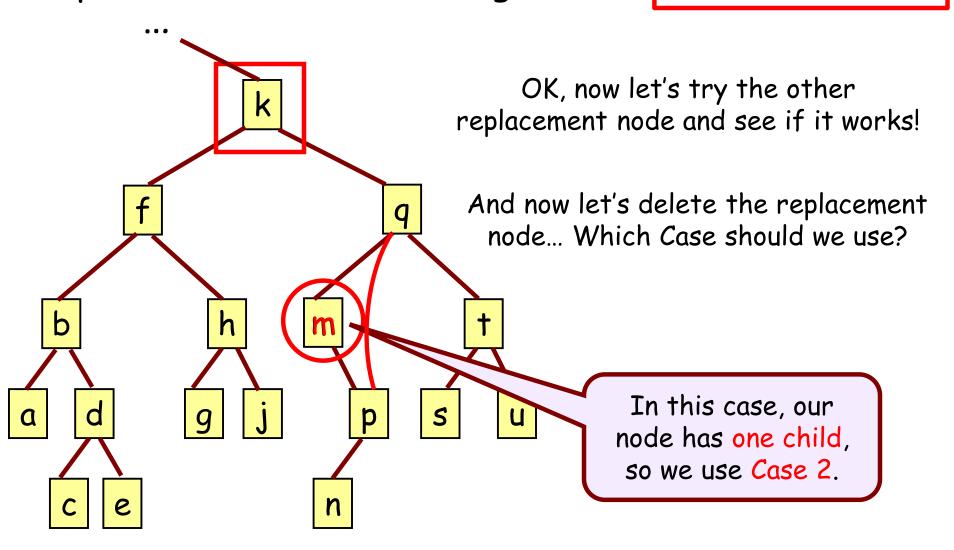

How? We want to replace k with either:

 K's left subtree's largest-valued child

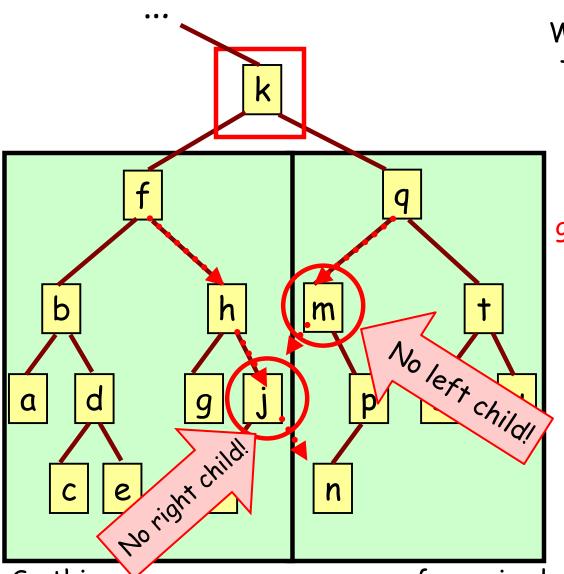

Or

2. K's right subtree's smallest-valued child

So we pick one, copy its value up, then delete that node!

Step #2, Case #3 - Our Target Node has Two Children

So this ensures we can use one of our simpler deletion algorithms for the replacement!

Why is it guaranteed that our two replacement nodes have either zero or one child?

Well, we found the left subtree's maximum value by going all the way to the right...

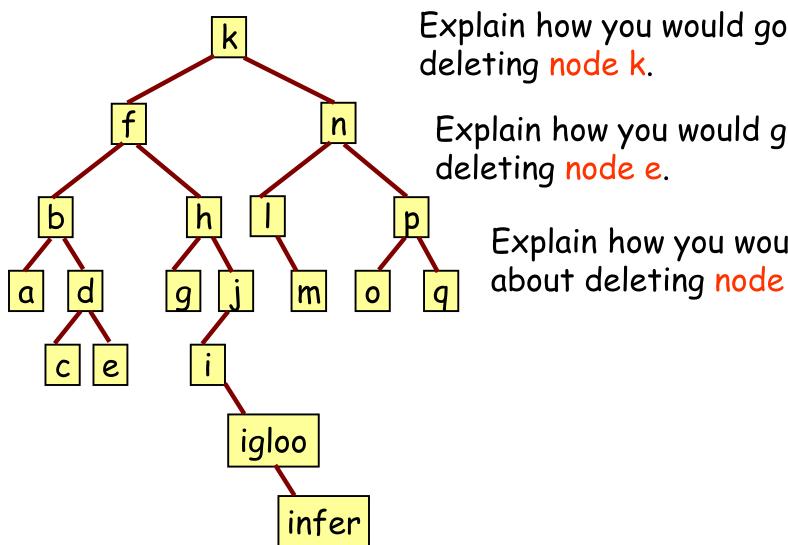

So by definition, it can't have a right child!

Either it has a left child or no children at all...

The same holds true for the smallest value in our right subtree!

By definition, it can't have a left child!

Deletion Exercise

Explain how you would go about

Explain how you would go about

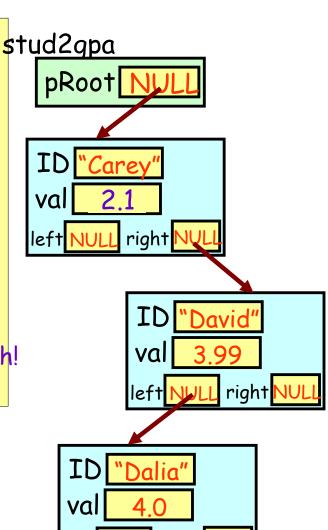

Explain how you would go about deleting node i.

Where are Binary Search Trees Used?

Remember the STL map?

```
#include <map>
using namespace std;
main()
  map<string,float> stud2qpa;
  stud2gpa["Carey"] = 3.62; // BST insert!
  stud2gpa["David"] = 3.99;
  stud2gpa["Dalia"] = 4.0;
  stud2gpa["Carey"] = 2.1;
  cout << stud2gpa["David"]; // BST search!
```

It uses a type of binary search tree to store the items!

Where are Binary Search Trees Used?

The STL set also uses a type of BSTs!

```
#include <set>
using namespace std;
main()
{
  set<int> a; // construct BST
  a.insert(2);
                   // insert into BST
  a.insert(3);
  a.insert(4);
  a.insert(2);
  int n;
 n = a.size();
 a.erase(2);
                  // delete from BST
```

The STL set and map use binary search trees (a special balanced kind) to enable fast searching.

Other STL containers
like multiset and
multimap also use binary
search trees.

These containers can have duplicate mappings. (Unlike set and map)

Huffman Encoding: Applying Trees to Real-World Problems

Huffman Encoding is a data compression technique that can be used to compress and decompress files (e.g. like creating ZIP files).

Background

Before we actually cover Huffman Encoding, we need to learn a few things...

Remember the ASCII code?

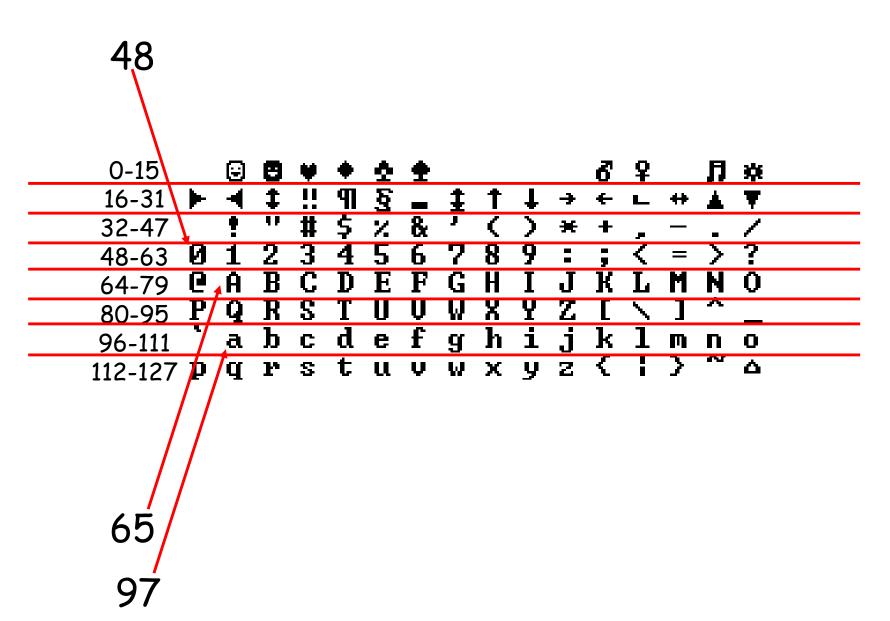

ASCII

Computers represent letters, punctuation and digit symbols using the ASCII code, storing each character as a number.

When you type a character on the keyboard, it's converted into a number and stored in the computer's memory!

The ASCII Chart

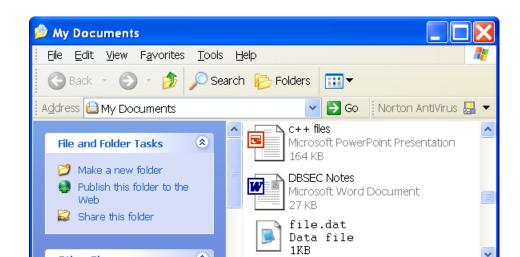

Computer Memory and Files

So basically, characters are stored in the computer's memory as numbers...

```
main()
{
    char data[7] = "Carey";

    ofstream out("file.dat");
    out << data;
    out.close();
}</pre>
```

Similarly, when you write data out to a file, it's stored as ASCII numbers too!

Bytes and Bits

Now, as you've probably heard, the computer actually stores all numbers as 1's and 0's (in binary) instead of decimal...

Each character is represented by 8 bits.

Each bit can have a value of either 0 or 1 (i.e. 1 = high voltage and 0 = low voltage)

Binary and Decimal

Every decimal number has an equivalent binary representation (they're just two ways of representing the same thing)

Decimal Number	Binary Equivalent
0	0000000
1	0000001
2	0000010
3	0000011
4	00000100
•••	•••
255	1111111

So that's binary...

Consider a Data File

Now lets consider a simple data file containing the data:

"I AM SAM MAM."

As we've learned, this is actually stored as 13 numbers in our data file:

73 32 65 77 32 83 65 77 32 77 65 77 46

And in reality, its really stored in the computer as a set of 104 binary digits (bits):

01001001 00100000 01000001 01001101 00100000 01010011 01000001 01001101 00100000 01001101 01000001 01001101 00101110

(13 characters * 8 bits/character = 104 bits)

Data Compresion

So our original string "I AM SAM MAM." requires 104 bits to store on our computer... OK.

01001001 00100000 01000001 01001101 00100000 01010011 01000001 01001101 00100000 01001101 01000001 01001101 00101110

The question is:

Can we somehow reduce the number of bits required to store our data?

And of course, the answer is YES!

Huffman Encoding

To compress a file "file.dat" with Huffman encoding, we use the following steps:

- 1. Compute the frequency of each character in file.dat.
- 2. Build a Huffman tree (a binary tree) based on these frequencies.
- 3. Use this binary tree to convert the original file's contents to a more compressed form.
- 4. Save the converted (compressed) data to a file.

Step #1: Compute the frequency of each character in file.dat. (i.e. compute a histogram)

FILE.DAT

I AM SAM_MAM.

```
'A' 3
'I' 1
'M' 4
'S' 1
Space 3
Period 1
```

Step #2: Build a Huffman tree (a binary tree) based on these frequencies:

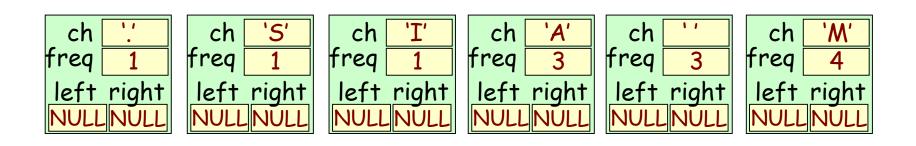

A. Create a binary tree leaf node for each entry in our table, but don't insert any of these into a tree!

freq

121

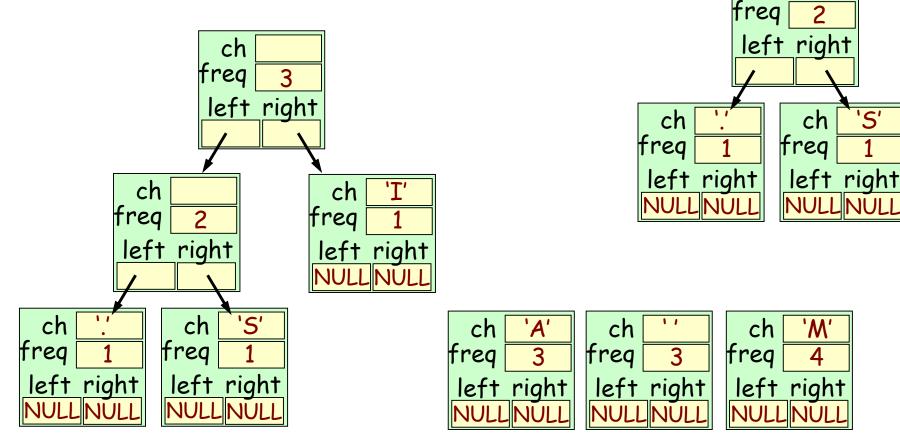

left right

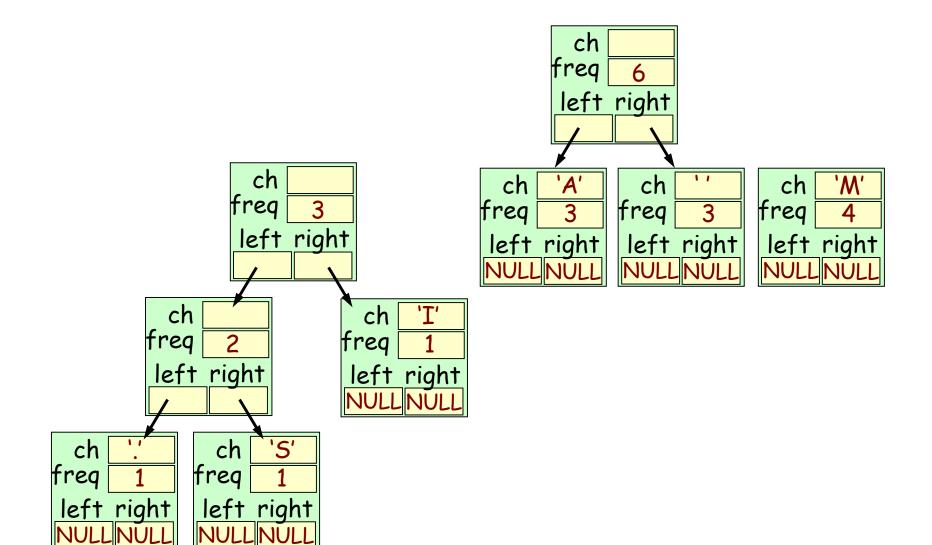

- B. While we have more than one node left:
 - 1. Find the two nodes with lowest freqs.
 - 2. Create a new parent node.
 - 3. Link the parent to each of the children.
 - 4. Set the parent's total frequency equal to the sum of its children's frequencies.
 - 5. Place the new parent node in our grouping.

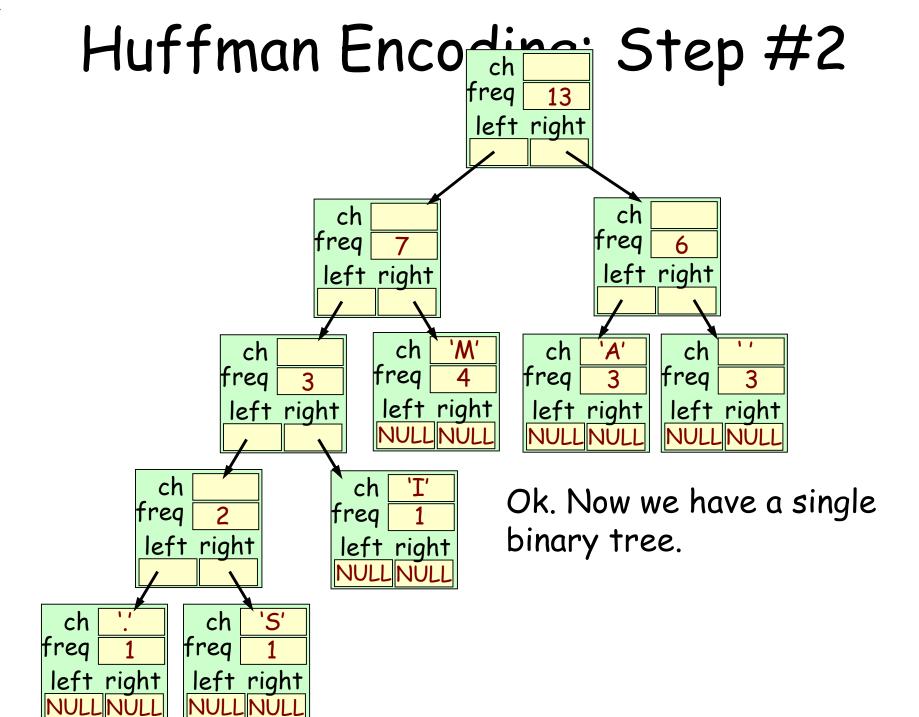

Step #2: Build a Huffman tree (a binary tree) based on these frequencies:

A. Create a binary tree leaf node for each entry in our table, but don't insert any of these into a tree!

Step #2: Build a Huffman tree (a binary tree) based on these frequencies:

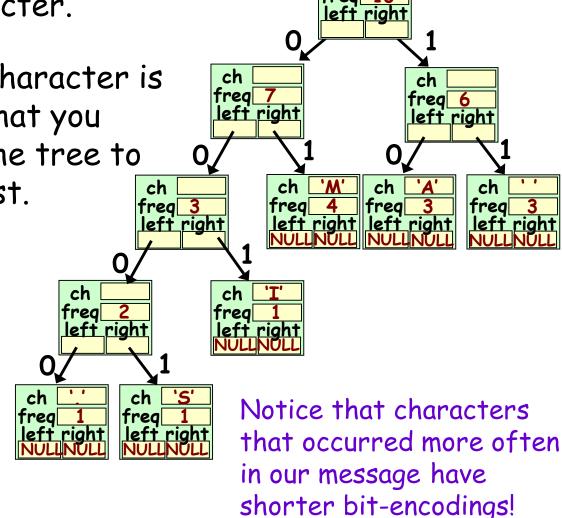

A. Create a binary tree leaf node for each entry in our table, but don't insert any of these into a tree! freq 13 B. Build a binary tree from the leaves. left right C. Now label each left edge with a "O" and each right edge with a "1" ch ch freq frea 6 <u>left riaht</u> left right ch ch ch freq 3 **frea** frea <u>left right</u> riaht | left riaht ch ch frea <u>left riaht</u> ch freq frea

Now we can determine the new bitencoding for each character.

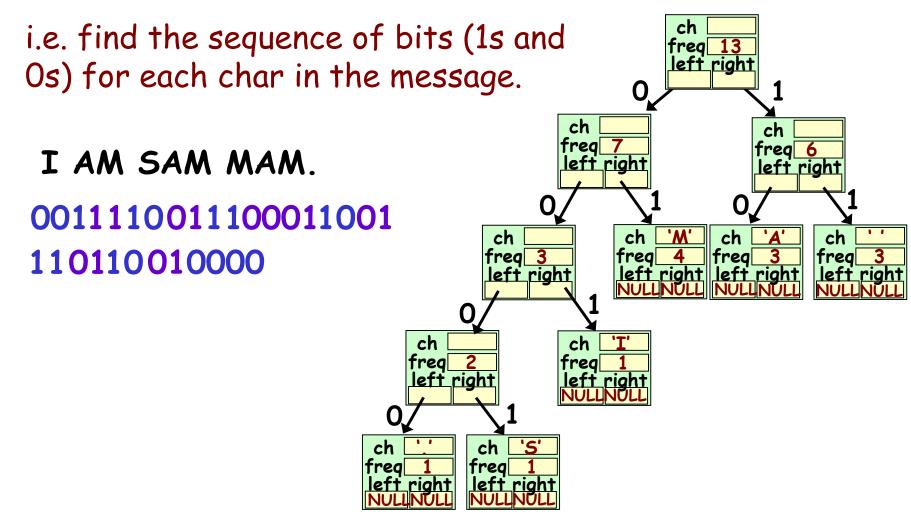

The bit encoding for a character is the path of 0's and 1's that you take from the root of the tree to the character of interest.

For example:

S is encoded as 0001
A is encoded as 10
M is encoded as 01
Etc...

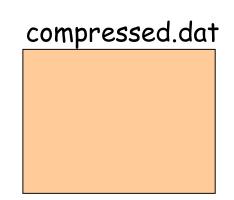

Step #3: Use this binary tree to convert the original file's contents to a more compressed form..

Step #4: Save the converted (compressed) data to a file.

001 1110 011 100 011 0011 1011 0 010 000

Notice that our new file is less than four bytes or 31 bits long!

originalfile.dat

01001001 00100000 01000001 01001101 00100000 01010011 01000001 01001101 00100000 01001101 01000001 01001101 00101110 Our original file is 13 bytes or 104 bits long!

We saved over 69%!

Ok... So I cheated a bit...

compressed.dat

```
Encoding:
A' = 10''
" = "11"
'M' = "01"
'I' = "001"
'.' = "0000"
'S' = "0001"
Encoded Data:
  0011110
 01110001
 10011101
 10010000
```

If all we have is our 31 bits of data... its impossible to interpret the file!

Did 000 equal "I" or did 000 equal "Q"? Or was it 00 equals "A"?

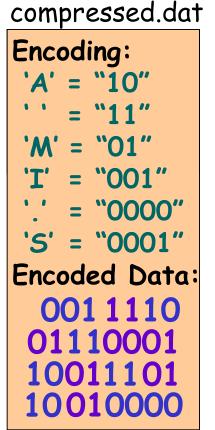

So, we must add some additional data to the top of our compressed file to specify the encoding we used...

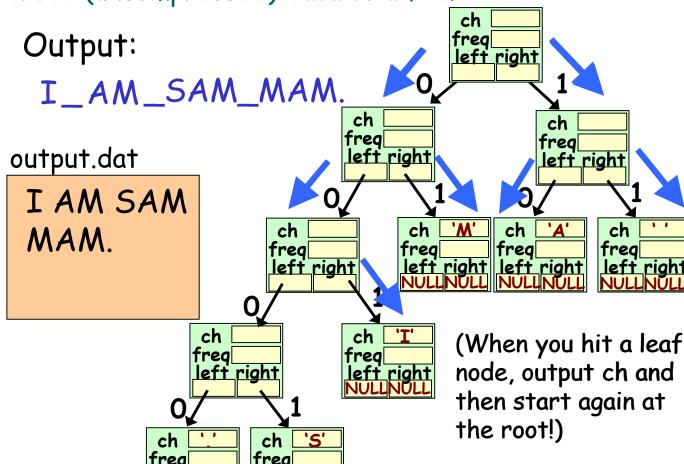

Now clearly this adds some overhead to our file...

But usually there's a pretty big savings anyway!

Decoding...

- 1. Extract the encoding scheme from the compressed file.
- 2. Build a Huffman tree (a binary tree) based on the encodings.
- 3. Use this binary tree to convert the compressed file's contents back to the original characters.
- 4. Save the converted (uncompressed) data to a file.

Question:

What happens if we insert the following values into a binary search tree?

5, 10, 7, 9, 8, 20, 18, 17, 16, 15, 14, 13, 12, 11

Right! We get an unbalanced tree!

Question:

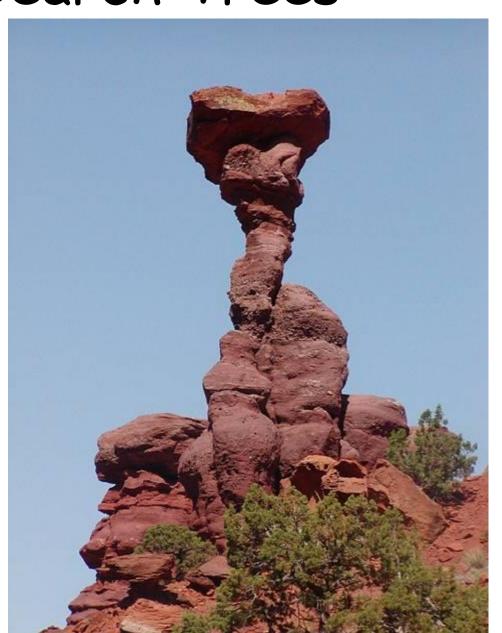

What is the approximate big-oh cost of searching for a value in this tree?

O(N)... YUCK!

In real life, BSTs often end up looking just like our example, especially after repeated insertions and deletions.

It'd be nice if we could come up with an improved BST ADT that always maintains its balance.

This would ensure that all insertions, searches and deletions would be $O(\log n)$.

Well, guess what?

CS nerds have come to the rescue!

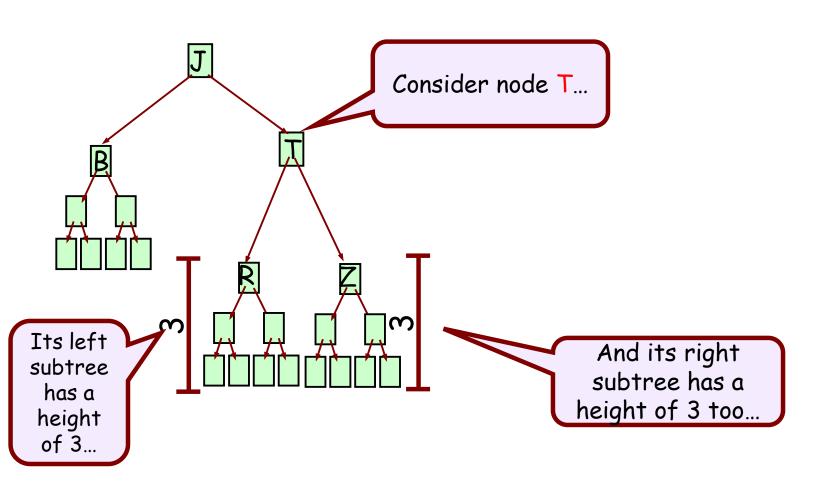

They've invented numerous improved binary search tree ADTs like 2-3 Trees, Red-Black Trees, and AVL Trees.

These BST variations work (mostly) just like a regular binary search tree...

but every time you add/delete a value, they automatically shift the nodes around so the tree is balanced!

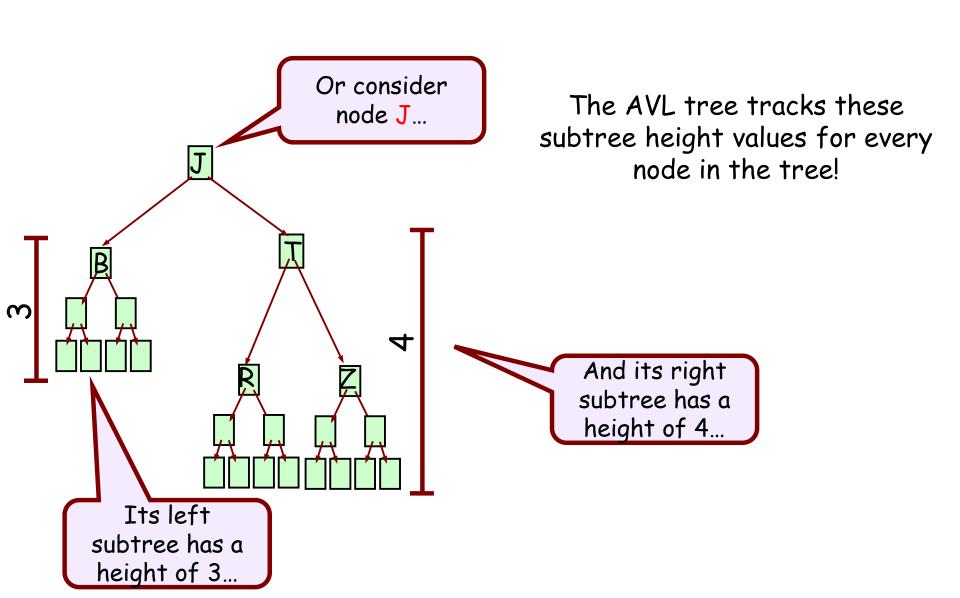

Balancing a Tree On Insertion

For example, the AVL Tree tracks the height of ALL subtrees in the BST.

Balancing a Tree On Insertion

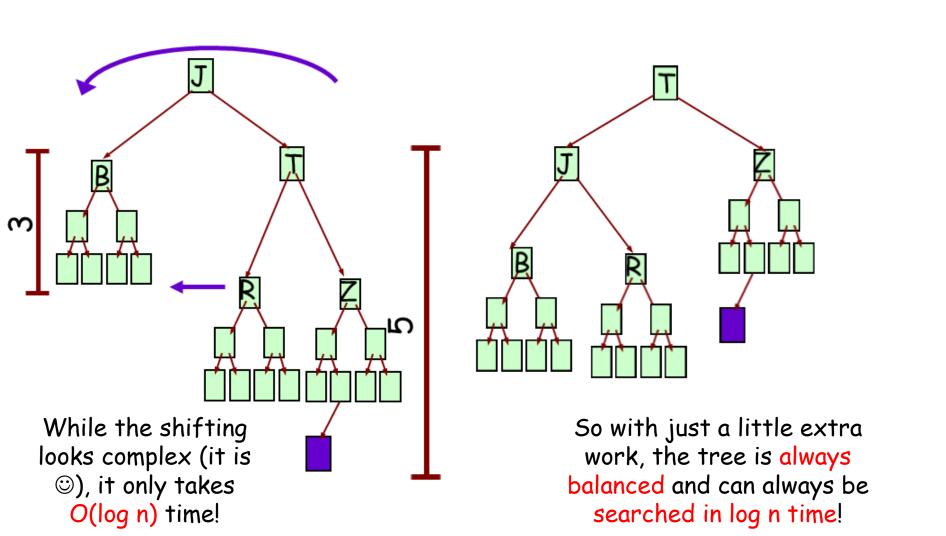

For example, the AVL Tree tracks the height of ALL subtrees in the BST.

For example, the AVL Tree tracks the height of ALL subtrees in the BST.

After an insertion/deletion, if the height of the subtrees under any node is different by more than one level...

Then the AVL algorithm shifts the nodes around to maintain balance.

You don't need to know the gory details of any of these balanced BSTs for your final or projects.

Just remember, that balanced BSTs are always O(log n) for insertion and deletion.

And if you're ever in a job/internship interview and are asked a BST question...

Always make sure to ask the interviewer if you may assume the BST is balanced!

It could make or break your interview!
